ABSTRACT

In 2006–2007, an unusually high number of harbor porpoises (*Phocoena phocoena*) stranded along the Washington and Oregon coastlines. Spatiotemporal analyses were used to examine their ability to detect clusters of porpoise strandings during an unusual mortality event (UME) in the Pacific Northwest using stranding location data. Strandings were evaluated as two separate populations, outer coast and inland waters. The presence of global clustering was evaluated using the Knox spatiotemporal test, and the presence of local clusters was investigated using a spatiotemporal scan statistic (space–time permutation). There was evidence of global clustering, but no local clustering, supporting the hypothesis that strandings were due to more varied etiologies instead of localized causes. Further analyses at subregional levels, and concurrently assessing environmental factors, might reveal additional geographic distribution patterns. This article describes the spatial analytical tools applied in this study and how they can help elucidate the spatiotemporal epidemiology of other UMEs and assist in determining their causes. More than one spatial analytical technique should be used if the study objective is to detect and describe clustering in time and space and to generate hypotheses regarding causation of marine mammal disease and stranding events.

Key words: epidemiology, harbor porpoise, GIS, *Phocoena phocoena*, spatiotemporal analyses, unusual mortality event.

Recent outbreaks of disease in humans and animals have motivated public health agencies and researchers to develop early disease outbreak detection systems utilizing nondiagnostic information (Kallen *et al.* 1985, Norström *et al.* 2000, Mostashari *et al.* 2003). Establishing these systems can involve many challenges relative to data collection, analytical methods, and response. Analytical challenges include dealing with unknown time, place, and size of an outbreak, trying to adjust for natural spatial and temporal variations, and the lack of suitable population-at-risk data. While detection of disease clustering in time or space may be accomplished by mapping or plotting cases as a time series, it may be difficult to detect and visualize the interaction between time and space. The use of geographic information systems (GISs) and spatial statistical analyses is needed to fully explore time–space clustering of disease and mortality events precisely (Ward and Carpenter 2000a). GIS and spatial epidemiological analyses have been used in several applications in marine mammal disease research, including mapping of strandings to demonstrate disease and mortality events (Dietz *et al.* 1989, Harris and Gupta 2006), surveillance and monitoring of diseases (Jores *et al.* 2008), disease cluster detection (Miller *et al.* 2004), identification of environmental predictors of disease in wildlife populations (Miller *et al.* 2002), risk assessments (Hung *et al.* 2004, 2007), and modeling the spread and impact of disease (Norman 2008).

Increased effort to examine live- and dead-stranded marine mammals has helped to improve our knowledge of mortality rates and causes, allowing a better understanding of population threats and stressors, as well as our ability to determine when a stranding situation is “unusual” as seen in strandings involving *Toxoplasma gondii*, *Cryptococcus gattii*, and morbilliviruses (Gulland *et al.* 2002, Kreuder *et al.* 2003, Miller *et al.* 2004, Norman *et al.* 2011, Rowles *et al.* 2011). Understanding and investigating marine mammal unusual mortality events (UMEs), which are unexpected strandings that involve a substantial die off of a marine mammal population, is important because these events can serve as indicators of ocean health, giving insight into larger environmental issues, which may have implications for human health and animal welfare (Gulland 2006). Investigations of UMEs and the formation of a Working Group on Marine Mammal Unusual Mortality Events (WGMMUME) were mandated by Title IV of the U.S. Marine Mammal Protection Act, developed in 1992 in response to growing concerns about marine mammal die offs (Marine Mammal Protection Act 1992). The WGMMUME has criteria for declaring a UME, which help identify stranding events that are unusual (Gulland 2006).

In recent years, efforts to examine stranded marine mammal carcasses in order to better understand population threats and stressors have increased (Mignucci-Giannoni *et al.* 2000, Evans *et al.* 2005, de la Riva *et al.* 2009). Most analytical methods used to investigate strandings involve necropsies, mapping, and some use of GIS and spatial statistics (Kreuder *et al.* 2003, Greig *et al.* 2005, Harris and Gupta 2006). These geospatial methods are useful for helping to determine possible causes of strandings, but have not been applied to investigations of large-scale mortality events such as UMEs. The application of spatial analytical methods may be used in the context of UMEs to explore the interaction of space and time during mass strandings and potentially help identify or generate hypotheses as to the factor(s)

Figure 1. Harbor porpoise (*Phocoena phocoena*) strandings (▲) during a UME in the Pacific Northwest (2006–2007).

that contributed to the event. Strandings may be mapped, spatially and temporally analyzed, and used to model future events and develop surveillance and monitoring programs for marine mammal diseases (Norman 2008). Here, the application of spatial analytical methods for UME data was evaluated using data from a harbor porpoise (*Phocoena phocoena*) UME in the Pacific Northwest.

In the Pacific Northwest (Oregon and Washington), harbor porpoises are divided into two stocks: Washington Inland Waters and Oregon/Washington Coast Stock (Carretta *et al.* 2007), and are found in coastal waters of Washington and Oregon year-round (Fig. 1). Although no reliable data exist for harbor porpoise population trends in Oregon, Washington, or British Columbia, uncorrected estimates of abundance for the Oregon/Washington coast stock did not differ significantly between 1997 ($O = 11,599$) and 2002 ($O = 11,036$) ($P = 0.76$), whereas uncorrected abundance estimates for the Washington inland stock significantly increased from 1996 to 2002/2003 (1,025 to 3,123; $P < 0.0001$) (Calambokidis *et al.* 1997, Laake *et al.* 1998, Carretta *et al.* 2007).

Since the 1970s, harbor porpoise stranding numbers in Oregon and Washington remained fairly consistent at ~ 10 –25 per year (Norman *et al.* 2004b) despite increased reporting effort. In British Columbia, harbor porpoise strandings steadily increased since 1978 with increased reporting effort (Baird and Guenther 1995). In 2003, the number of strandings in Washington increased substantially to 34 (Norman *et al.* 2004a, 2004b) and then dramatically increased in 2006 and 2007, with 64 and 50, respectively, being recorded. Due to the increased number of strandings reported

in 2006 compared to years prior, and after consultation with the WGMMUME, a UME was declared in the Pacific Northwest on 3 November 2006 to facilitate the coordination of response and investigative efforts within the Northwest Region Stranding Network.

The UME, involving 114 harbor porpoises, continued through the end of 2007. The UME was officially declared over by the end of May 2008; however, any stranded porpoises documented during the first few months of 2008 were not included in the analyses as this time period was only used for post-UME monitoring of porpoise strandings (NOAA Fisheries, unpublished data). In addition to investigating the UME through necropsies, histopathology, and contaminant analyses, the need to spatially and temporally analyze the strandings was recognized. In this methodological article, we present and illustrate the Knox and the space–time permutation scan methods, to test for spatiotemporal clustering of harbor porpoise UME strandings over the entire study area (globally), and at more localized areas (locally), respectively (Knox 1964, Kulldorff *et al.* 2005). The purpose of this study was to test whether during this UME there were significant spatial and/or temporal clusterings of stranded porpoises in the outer coast *vs.* inland waters populations.

METHODS

Porpoise Data Set

Harbor porpoise carcasses were recovered through NOAA Fisheries' Northwest Region Marine Mammal Stranding Network, encompassing Oregon and Washington and made up of cooperating stranding response organizations. Each porpoise stranding location was determined by geographic positioning expressed in latitude and longitude at the time of carcass recovery. Stranding date, county, state, inland waters or outer coast (for Washington State) were recorded, and when possible, sex and age class. Carcasses were processed as soon as possible (within 24–48 h of reporting). Age class was determined at necropsy by measurement of overall straight length (tip of beak to fluke notch), following the age class divisions in Read and Tolley (1997). Necropsies, as well as microscopic examination of major tissues, were performed on almost all of the carcasses by experienced individuals (NOAA Fisheries, unpublished data).

Geographic Information System

GIS has generally been used to analyze the relationships between potential risk factors and the occurrence of disease (incidence or prevalence) on a geographical basis through visual interpretation of maps (Ward and Carpenter 2000*b*). A disadvantage of data visualization is that it cannot indicate whether an aggregation of cases is actually due to a large number of cases or just to a large number of individuals in an area (Moore and Carpenter 1999).

For this study, a GIS (ArcGIS, version 9.3.1, ESRI, Redlands, CA) was used to spatially display stranding data points, along with maps of strandings by age class and sex (projection: World GCS 1984). A distinction between the inland waters and outer coast was made to reflect the differences in oceanic conditions and porpoise stocks between the two regions. Because harbor porpoise movements (Hanson 2007*a*) and intermixing rates are restricted in the North Pacific, and in following a risk adverse

management strategy, two stocks are recognized: the Oregon/Washington Coast stock, occurring between Cape Blanco, Oregon, and Cape Flattery, Washington, and the Washington Inland Waters stock, in waters east of Cape Flattery (Fig. 1). Based on the geographic delineation of the two stocks of harbor porpoises, each spatiotemporal analysis was performed twice, once each for the two bodies of water.

SpatioTemporal Tests

Disease or mortality events may cluster in time and/or space, but not necessarily be due to local transmission from a contagious process. For instance, a global epidemic or event that has obvious temporal clustering may display a random spatial pattern. On the other hand, clustering might be noted in a specific geographic location, although these events may not display a specific temporal pattern. The methods described here focus on detecting clusters in space and time; in other words, to evaluate whether events that are close throughout the study region are also close throughout the study time period, and *vice-versa* (Ward and Carpenter 2000a).

In this study, two spatiotemporal cluster detection tests were performed to examine for clusters both globally and locally. Global indices of spatial association evaluate the propensity of spatial clustering across an entire region, while local indices of spatial association detect patterns in more locally defined geographic units (*e.g.*, counties) that acutely deviate from neighboring units. Both tests use case (stranding) data and adjust for purely spatial and purely temporal clustering, and thus avoid confounding by differential reporting effort by location or season. The Knox test, a global cluster detection test, detects space–time interactions by categorizing points into near and far in space *vs.* near and far in time, based on critical space and time distances set by the user, and is not affected by nonuniform underlying population densities (Knox 1964). SaTScan is an analytic method that has been widely used for local cluster detection, and evaluation of outliers (Jackson *et al.* 2009).

Global Cluster Detection

Global clustering tests evaluate the relationship between cases and controls; clustering is present if cases are closer to other cases than they are to controls. Alternatively, clustering can also be determined by distance between cases if controls are not available (Kulldorff and Nagarwalla 1995). The Knox test was used in this analysis to separately test for global clusters within the two study areas (Knox 1964) using the SSTAT Spatial Statistics Program (version 4.70, University of California, Davis, CA). While the test has been used to investigate factors influencing outbreaks of disease in fish through cluster detection (Georgiadis *et al.* 2001), it has not yet been applied to marine mammal stranding analyses. It calculates the spatial and temporal distance separations of all strandings (case pairs). First, critical distances are determined, representing the space or time distance where disease transmission is believed to be possible. The critical time distance may represent the incubation period, and the space distance may represent host or vector (or current and wind) movement within that critical time period. After these critical periods are defined, the proportion of case pairs “close in time” is multiplied by the proportion of case pairs “close in space” to give the expected proportion of case pairs “close in time and space.” The resulting expected proportion is multiplied by the total number of case pairs to give the number of case pairs expected to be both close in space

and time. This result is compared with the observed number of case pairs that were close in space and time. If the observed number exceeds the expected, this indicates clustering. The probability of observing at least the number of observed case pairs that are close in time and space is calculated to determine significance (Carpenter 2001).

The total number of case pairs is $n(n - 1)/2$, where n equals the number of cases (strandings). The number of case pairs examined in this study was 903 [(43 × 42)/2], and 2,485 [(71 × 70)/2], in the inland and outer waters, respectively. For this analysis, the following critical distances and times were selected: 1, 3, 5, 10 km and 7, 14, 21 d, respectively, to specify space and time separations between strandings, which are believed to be sufficiently close for an association between the strandings, that may imply either disease transmission between cases or sharing of a common stranding source. The number of stranding pairs that were less than or equal to the critical values was compared with the expected using the following equation:

$$P(X \geq k) = \sum_{i=k}^{\infty} \frac{e^{-\lambda} \lambda^i}{i!} = 1 - \sum_{i=0}^{k-1} \frac{e^{-\lambda} \lambda^i}{i!},$$

where k is the number of observed stranding pairs that were close (less than the critical distance) in both space and time and λ is the expected number of stranding pairs that were close in both space and time and is calculated as the proportion of stranding pairs that were close in space, times the proportion of stranding pairs that were close in time, times the number of stranding pairs.

Local Cluster Detection

Localized clustering tests divide the study area into subsets, called geographic units, which can be used to specify significantly elevated rates or cases of disease or events in these units, and identify these areas as a cluster. In this study, we present a prospective space–time permutation scan statistic for which population-at-risk data are not required, and which can be used for the early detection of disease outbreaks when only case numbers (no controls) are available. The scan may be used prospectively to regularly scan a geographical region for outbreaks or unusual events of any location and any size. For each location and size, potential one-day as well as multi-day outbreaks can be observed, in order to quickly detect a rapidly intensifying outbreak and still have sufficient power to detect a gradually emerging outbreak by combining data from multiple days (Kulldorff *et al.* 2005). Natural space by time interaction in many syndromic surveillance data sources may be due to factors other than disease outbreak such as foraging behavior, migration, currents, and other natural phenomena (Kulldorff *et al.* 2005).

Recent examples of applications of this to detect spatiotemporal disease clustering and strandings in wildlife and domestic animals include assessing the spatial distribution of chronic wasting disease in white-tailed deer (*Odocoileus virginianus*) in Wisconsin (Joly *et al.* 2003), evaluating the prevalence of bovine tuberculosis in wild badgers (*Meles meles*) in Ireland (Olea-Popelka *et al.* 2003), and assessment of causes of mortality in stranded southern sea otters in California (*Enhydra lutris nereis*) (Kreuder *et al.* 2003).

A spatiotemporal permutation model was used to identify local spatiotemporal clusters (SaTScan version 7.0, Martin Kulldorff, Boston, MA; Kulldorff and Nagarwalla 1995, Kulldorff 1997, Kulldorff *et al.* 2005). SaTScan has been widely used for cluster detection on aggregated count data. For each centroid (*i.e.*, geographic unit), many windows (circles or ellipses) are constructed, with varying sizes (and angles) sharing the same centroid. SaTScan was only evaluated with elliptical windows in this analysis because for most situations, the elliptic version has better power and precision compared with circular windows (Jackson *et al.* 2009). Through its continuously moving “window,” the resulting scan statistic considers different sized aggregations of cases, thereby avoiding arbitrary geographical aggregation of the data. The number of observed strandings in a cluster was compared to what would have been expected if the spatial and temporal locations of all the strandings were independent of each other so that there was no space–time interaction. The statistic utilizes a probability model to calculate the observed number of strandings (C) using only cases of strandings (*i.e.*, no “controls”) in a specific area (s) during day (d):

$$C = \sum_s \sum_d C_{sd}.$$

For each stranding and day, the expected number of cases ($\mu_{sd} \frac{1}{C}$) is calculated, conditioning on the observed marginals:

$$\left(\sum_s C_{sd} \right) \left(\sum_d C_{sd} \right).$$

A cluster of strandings would be detected in a particular geographic area if, during a specific time period, the area had a higher than expected number of strandings than surrounding areas. An infinite number of overlapping cylinders, jointly covering the entire study area, are obtained, with each cylinder reflecting a potential cluster, differing in size and shape. The likelihood function was maximized over all windows, identifying the window that constituted the likeliest stranding cluster. This is the cluster least likely to have occurred by chance. The likelihood ratio for this window is the maximum likelihood-ratio test statistic. The statistic’s distribution under the null hypothesis and corresponding P -value were obtained by repeating the same analytic exercise on a large number of randomly selected replications of the data set generated under the null hypothesis (in a Monte Carlo simulation), resulting in 999 random data set replications being generated, where stranding times were randomly assigned to each stranding location (Ward and Carpenter 2000*b*). Clusters were said to be statistically significant if the rank of the likelihood function of the observed strandings was among the 50 largest simulated values, that is, $P \leq 0.050$.

RESULTS

A total of 114 harbor porpoises stranded from January 2006 through December 2007, 43 (37.8%) in the inland waters of Puget Sound and the Strait of Juan de Fuca and 71 (62.2%) on the outer coast of Washington/Oregon (Fig. 1). Females constituted 35 (30.7%) of the strandings, males 43 (37.7%), and unknown sex 36 (31.6%). Age class distribution was as follows: 34 (29.8%) adults, 36 (31.6%)

Figure 2. Harbor porpoise (*Phocoena phocoena*) strandings by month and age class during a UME in the Pacific Northwest (2006–2007).

subadults, 41 (36.0%) calves, and 3 (2.6%) were of unknown age class. Necropsies, conducted on 75 of 114 individuals, representing all age classes showed no consistent lesions that would have accounted for an unusual number of mortalities (NOAA Fisheries, unpublished data). Although there was an apparent increase in the number of strandings observed during the summer (June–August) compared to other seasons, it was not statistically significant (Kruskal-Wallis, $\chi^2 = 3.000$, $df = 3$, $P = 0.392$), and therefore no trend was detected (Fig. 2). Calves stranded more than other age classes, but not significantly (Kruskal-Wallis, $\chi^2 = 3.000$, $df = 3$, $P = 0.392$), and were heavily concentrated in the inland waters of Puget Sound. Statistically significant global clusters ($P \leq 0.050$) were detected in inland waters for the following critical time/distances (days/kilometers): 14/1 ($P = 0.022$), 21/1 ($P = 0.041$), 7/3 ($P = 0.050$), and 14/3 ($P = 0.041$). These critical pairs were further evaluated and found to be comprised of two adult males that stranded 7 d apart in Sekiu, Washington (they were caught in the same commercial gill net and were recovered and reported by the fishermen), and a calf that stranded 5 d before an adult female at nearly the same location (Blaine, Washington). No significant clusters were detected at the local level for either the outer coast or inland water strandings, $RR = 4.45$, $P = 0.158$ and $RR = 4.44$, $P = 0.549$, respectively.

DISCUSSION

The primary goal of this manuscript was to use the stranding event example to illustrate the utility and application of GIS and spatiotemporal analyses as part of an

unusual stranding event investigation and to better understand the epidemiology of these incidents. A notable finding was the elevated number of stranded calves relative to other age classes (Read and Tolley 1997) (Fig. 2). Harbor porpoises normally calve from May through June, which could partially account for the elevated number of stranded calves (Bjørge and Tolley 2008). If harbor porpoise population levels recently increased, then an increase in calf strandings relative to other years would be observed. The late spring and summer pattern of strandings is consistent with previously reported harbor porpoise stranding patterns (Norman *et al.* 2004a), likely due to seasonality of the animals' movements and foraging habitat, and from increased reporting effort during better weather conditions and visitors to the coastline (Hanson 2007b). A low proportion of cetacean deaths actually end up as strandings (<10%), so even a small change in the proportion of deaths that wash ashore may appear as a significant change in strandings numbers, even if overall mortality has not changed (Williams *et al.* 2011). The magnitude of misrepresentation of stranding numbers when presenting observed carcass counts may be tempered by qualifying these numbers based on the species in question, its abundance, and survival rates (Williams *et al.* 2011).

When analyzing marine mammal stranding data, findings must be interpreted with caution as it cannot always be determined if the animal died in the vicinity of the stranding location, or elsewhere and then washed up at the site. However, it is expected that stranding patterns are already biased toward nonsignificant spatial patterns due to the influence of carcass drift, current, wind, or reporting effort. Therefore, the finding of any significant clustering during analyses warrants further investigation. Possible etiologies of this broad-scale event are discussed elsewhere (NOAA Fisheries, unpublished data), but briefly, might include changes in porpoise distribution in response to changes in prey distribution or predator avoidance, feeding habitat shifts, and carcass drift from wind and currents. Critical distances and times between a case (stranding) pair represent space and time separations where there may have been disease transmission or common exposure to two cases. The adult/calf pair cluster may have been related, but needs confirmation by genetic analysis. The significance of the two adult males stranding at the same location within 8 d of each other is presently unknown. The lack of evidence for localized clustering would likely exclude more contained etiologic causes such as harmful algal blooms or point-source events (*e.g.*, bacterial outbreak or oil spill), as evidenced by lack of reported disease outbreaks shortly before or during the UME, and lack of pathological evidence of multiple deaths due to a single or predominant etiology.

In this study, stranding data were analyzed for two separate areas, inland waters and outer coast, to account for differences in habitat and range of these two groups of porpoises (Carretta *et al.* 2007) as well as oceanographic differences between the two habitats. However, when space-time permutation models are utilized, spatial and temporal biases are greatly minimized, particularly when the study period is shorter than a few years (Kulldorff *et al.* 2005). Cluster analyses have been used to study the distribution of causes of death in California sea lions (*Zalophus californianus*) (Greig *et al.* 2005), the spatial relationship between *T. gondii* serological status and stranding location of southern sea otters (Miller *et al.* 2002), and show great potential for use in the study of marine mammal diseases and large-scale mortality events (Norman 2008). In other spatial analyses of marine mammal strandings and diseases, a single type of spatial test was used (scan statistic) (Miller *et al.* 2002, Kreuder *et al.* 2003, Greig *et al.* 2005). In contrast, this study combined both global and local spatiotemporal tests to assess the presence of clustering on both scales since no one

spatial analytical technique is considered better than others (Ward and Carpenter 2000b).

Methods used here to evaluate the presence of spatiotemporal clustering can be applied to other UME investigations to further explore stranding patterns and help elucidate potential causes of the event. Spatiotemporal tests are advantageous for use with stranding data in that they use only case data (control data not required), are not bound by population distribution assumptions, and adjust for purely spatial or purely temporal clustering, thereby eliminating potential confounding associated with data collection. To ensure sufficient study power, the Knox test was used to detect global clusters and the spatiotemporal scan statistic to detect local clustering. The Knox test has been used in veterinary epidemiology to examine *Salmonella* infections of horses, investigate fowl-cholera outbreaks in the Californian turkey industry, and to describe blowfly strike in Queensland sheep flocks (Carpenter *et al.* 1996, Paré *et al.* 1996, Ward and Armstrong 2000). Kulldorff *et al.* (1998) reported the power of the space–time scan statistic to be dependent on the shape of the cluster, number of cases in the data set, and the relative risk within and outside the cluster. They reported the space–time scan test had 80% power if the relative risk were 4.4 (similar to the values reported here) in order to detect a cluster of 10 cases. This study utilized well-established advantages of the space–time scan statistic such as adjusting for an inhomogeneous population density, searching for clusters without specifying their size or location in order to resolve preselection bias; delivering a single *P*-value, and using a likelihood ratio based statistic to take multiple testing into account (Viel *et al.* 2005).

A potential lack of power should be considered in studies that fail to detect space–time clustering when the sample size is <500 cases (Paré *et al.* 1996). A limitation of the Knox test is that it is heavily dependent on the critical time and space distances the researcher specifies. Ideally, these critical values should be selected based on known epidemiological characteristics of the disease or event of interest. In some cases, however, if the disease etiology and/or cause of stranding is unknown or poorly characterized, exploratory analyses can be useful. Contrary to being viewed as data “mining,” exploratory analyses can provide useful information on factors that may have contributed to the cluster of events and may be thought of as hypothesis-generating approaches (Ward and Carpenter 2000a). Another Knox test limitation is that the need to identify critical time and space distances also results in a loss of information, but is countered by the fact that the Knox test may be used for more qualitative data such as “near” *vs.* “far” spatial and temporal distances (Ward and Carpenter 2000a).

Advantages of the space–time permutation scan statistic method are that it requires only case data, is easy to use, makes minimal assumptions about the geographic location, time, or size of the outbreak or stranding event, while automatically adjusting for any natural purely spatial and purely temporal variation, and it allows adjustment for space by time interaction (Kulldorff *et al.* 2005). Another benefit is that it takes into account the linear nature of the outer coastline with an elliptical window to capture strandings along a linear coastline. An alternative to a circular window, the elliptical window shape provides a slightly higher power for true clusters that are long and narrow in shape, such as along a coastline. Lastly, this test also solves the problem of multiple testing when closely overlapping spatial areas and/or time intervals are being evaluated.

There are a number of limitations of the space–time permutation scan method. The method is highly sensitive to missing or incomplete data, which emphasizes

the need for good data quality checks and analytic adjustments during the analyses (Kulldorff *et al.* 2005). It is also important to note that the geographical boundary of the detected event is not necessarily the same as the boundary of the true event. The less geographically condensed the event is, the less power (sensitivity) there is to detect it. In spite of these limitations, the space–time permutation scan statistic has the ability to perform without population-at-risk data which is often the case in dealing with wild marine mammal populations, where these data may be hard to obtain (Kulldorff *et al.* 2005). The stranding data used in this study also have some limitations. Some strandings went undetected because carcasses did not wash ashore or were washed back out to sea or scavenged before being discovered and reported. Furthermore, some strandings may not be clustered by easily defined units of analysis, as in the case of a point-source exposure occurring at the site of an oil spill or algal bloom. Use of a geographic unit (*e.g.*, county) of stranding, rather than the stranding site itself, may provide greater power to detect nonpoint source-related unusual stranding events.

In conclusion, the results of the cluster detection tests indicate global clusters occurred throughout the strandings for both regions, suggesting that the cause(s) of mortality among these porpoises was not of a point-source type, but may have been generalized and varied toward a broader ecosystem-type source. Spatial epidemiology and GIS utilized during a UME investigation may help generate hypotheses as to the etiologic and geographic source(s) of contributors to strandings, or further refine and guide ongoing investigations of unusual mortalities. It would be ideal to be able to detect a UME in its early stages using spatial and temporal analytical tools; however, in the event that the cause(s) of a UME (that has already happened) is unknown, a retrospective analysis of the stranding data, such as this study, may give clues or generate hypotheses as to potential causes. Different types of spatial and temporal analytical tools may be applied prospectively to detect UMEs, or retrospectively analyze data on confirmed UMEs. In addition, spatiotemporal analytical tests could be used to analyze strandings not previously recognized as UMEs, to see if they were, in fact, unusual.

More than one spatial analytical technique should be used if the study objective is to detect and describe clustering in time and space and to generate hypotheses regarding causation of marine mammal disease and stranding events. It is also critical to consider the spatial and temporal model inherent in the techniques when interpreting results (Ward and Carpenter 2000a). These techniques add substantial information to disease and stranding investigations and provide the veterinary epidemiologist with a firm foundation on which to build causal hypotheses and implement more refined response and investigative strategies. When choosing a spatial analytical technique, ideally the investigator should determine the type of data to be analyzed (continuous, dichotomous or categorical, and point or area), what procedure will be examined (detection of clusters, interpolation, or diffusion), what spatial data are available, the appropriate scale for the analyses, existence of commercial software for the technique (*vs.* the necessity for custom programming), and the test's reported power. The challenge now is to employ these techniques as routine procedures within marine mammal disease and stranding investigation programs. Some issues that must be addressed in the future include the routine collection of spatial and temporal information from disease and stranding surveillance and monitoring programs, and the development of software that can be easily accessed, used and understood by veterinary epidemiologists and marine mammal researchers. Publication of more examples of the application of techniques to investigate spatial and

temporal clustering of disease in veterinary epidemiology will assist epidemiologists and statisticians in addressing these issues.

ACKNOWLEDGMENTS

The authors thank the stranding volunteers and individuals involved in the response and recovery of animals during the UME, including A. Traxler and the San Juan County Marine Mammal Stranding Network, the volunteers of the Central Puget Sound Marine Mammal Stranding Network, S. Murphy, K. Wilkinson, B. Norberg, L. Barre, the members of the UME Working Group, and the volunteers of the Northwest Region Marine Mammal Stranding Network. We are grateful to S. Raverty for conducting the majority of the histopathology and ancillary testing associated with this UME. Funding for collection and examination of the animals was provided by grants to Stranding Network members from the John H. Prescott Marine Mammal Rescue Assistance Grant Program, administered through the Office of Protected Resources (NOAA Fisheries). Valuable and constructive comments were received from J. Stein, NOAA Northwest Fisheries Science Center.
